

1 **Pedogenesis and clay mineralogy of a climolithotoposequence in Jazmurian**
2 **Watershed, central Iran**

3 **Saleh Sanjari¹, and Mohammad Hady Farpoor^{1*}**

4 **Abstract**

5 Topography, parent material, and climate are critical factors influencing pedogenesis and the clay
6 mineralogy of soils. There is a paucity of data regarding the soils and sediments of the Jazmurian
7 Watershed in south-central Iran. This study selected various landforms, including rock and mantled
8 pediments, alluvial fans, piedmont plains, lowlands, and playa, characterized by igneous and
9 sedimentary parent materials and situated within aquic, xeric, and aridic soil moisture regimes, to
10 investigate soil genesis and clay mineralogy in the region. The findings indicated that the most
11 significant soil development occurred on rock and mantled pediments, as well as on older alluvial
12 fan sediments, in contrast to the less developed soils found on younger alluvial fan deposits. The
13 clay minerals identified through X-ray diffraction (XRD) analyses included smectite, illite,
14 chlorite, palygorskite, and kaolinite. The presence of palygorskite in the sedimentary soils was
15 attributed to inheritance from the parent material, while in soils derived from igneous parent
16 material, palygorskite was formed through pedogenic processes. Pedogenic features associated
17 with calcium carbonate, such as coatings, infillings, and nodules, as well as clay coatings and
18 infillings, were observed in both aridic and xeric soil moisture regimes. The occurrence of clay
19 pedogenic features in the arid regions of the watershed may suggest a historical paleoclimate with
20 greater moisture availability. Conversely, lenticular shapes, interlocked plates, and gypsum
21 infillings were exclusively noted in the arid regions and lower elevations of the watershed,
22 reflecting the current arid climate. The study established a strong correlation between soil
23 formation and the factors of climate, parent material, and relief within the area.

24 **Keywords:** Central Iran, Geomorphic surface, Paleoclimate, Paleosols, Soil evolution.

25
26 **1. Introduction**

27 Soil formation and evolution influenced by soil-forming factors have been the focus of many
28 pieces of research (Badia et al., 2020; Owliaie et al., 2018; Wilson et al., 2017; Yousefifard et al.,

¹ Department of Soil Science, Faculty of Agriculture, Shahid Bahonar University of Kerman, P.O. Box: 76169-14111, Kerman, Islamic Republic of Iran.

* Corresponding author; e-mail: farpoor@uk.ac.ir

29 2015, Farpoor et al., 2012, Moazallahi and Farpoor, 2012; Saez et al., 2003). Soil genesis related
30 to geomorphology helps better understanding of soil forming factors and processes (Moghbeli et
31 al., 2019; Sanjari et al., 2011). Owliaie et al. (2018) reported the impact of parent material and
32 geomorphic position on physicochemical properties, clay mineralogy, and micromorphology of
33 soils, south western Iran.

34 Lithology, together with other soil forming factors is reported as a major factor affecting
35 pedogenesis (Wilson et al., 2017). Soil characteristics in northwest Iran affected by volcanic and
36 plutonic rocks were studied by Yousefifard et al. (2015). They found more evolution in soils
37 derived from volcanic rocks compared to plutonic ones. Soil properties and evolution were mainly
38 affected by particle size and mineralogy of parent material in soils of arid Kapehdagh Basin,
39 northeast Iran, which is an emphasis on the relationship between soil and parent material in that
40 area.

41 Climate has a major role on the weathering processes of parent material. Climatic variations
42 influence on the type and the rate of soil forming processes which in turn affect physicochemical
43 properties and clay mineralogy of soils (Phillips et al., 2008). Weathering is highly related to the
44 climate and trioctahedral minerals such as mica and chlorite may transform to dioctahedral smectite
45 due to the high rate of weathering (Egli et al., 2008). Soil evolution in Nevada was affected by
46 weathering rate and moisture regime (Elliot and Dorhan, 2009).

47 Soil minerals could be used to understand soil genesis (Graham and O'Geen, 2010), manage arid
48 and wet land soils (O'Geen et al., 2008), and interpret paleo environmental conditions (Sanjari et
49 al., 2012; Monafi, 2010; Khormali and Abtahi, 2003). Clay mineralogy of soils in Jiroft area,
50 central Iran showed that due to high water table, palygorskite stability decreased and smectite
51 dominated in soils from mantled pediment toward alluvial plain (Sanjari et al., 2011). In a soil
52 geomorphology study of the southern parts of central Iran, Sarmast et al. (2017) reported chlorite,
53 smectite, illite, palygorskite, and kaolinite clay minerals on different geomorphic positions.

54 Micromorphology is a useful complementary tool for soil morphology and evolution studies and
55 seems necessary to better classify and manage soils of an area (Stoops, 2003). In a soil
56 geomorphology study of Sirjan Playa, central Iran, Farpoor et al. (2012) reported calcite coatings
57 and infillings in pediments, but lenticular shape and interlocked plates of gypsum in piedmont plain
58 and playa landforms. Clay coating and infilling in the piedmont plain was attributed to the more
59 available humidity of the climate in the past by the same researchers. Soil micromorphology related

60 to geomorphic position in central Iranian soils was studied by Sarmast et al. (2019). They reported
61 clay (coating), calcite (nodule, coating, quazicoating, and infilling), anhydrite (nodule), gypsum
62 (lenticular, vermiform, and interlocked plates), and halite (coating) pedo-features in the area under
63 study.

64 Sixty watersheds were investigated in a study conducted by Krinsley (1970) in central Iranian
65 plateau and Jazmurian is among the most widespread playas reported in that report. Limited data
66 about soils and environmental factors in this playa are available. The only published report dates
67 back to the study on sediments of the area related to geomorphic positions using aerial photo
68 interpretations and limited field studies (Krinsley, 1970). Since climate, parent material, and
69 geomorphic position are hypothesized to affect soil genesis and evolution on one hand, and limited
70 data on soils of the study area are reported from the other hand, the present research was conducted
71 with the following objectives: to study 1) physicochemical soil properties, clay mineralogy, and
72 soil micromorphology in soils of the area, 2) the origin and distribution of clay minerals related to
73 the variation of soil forming factors, 3) soil development along a climotopolithosequence.

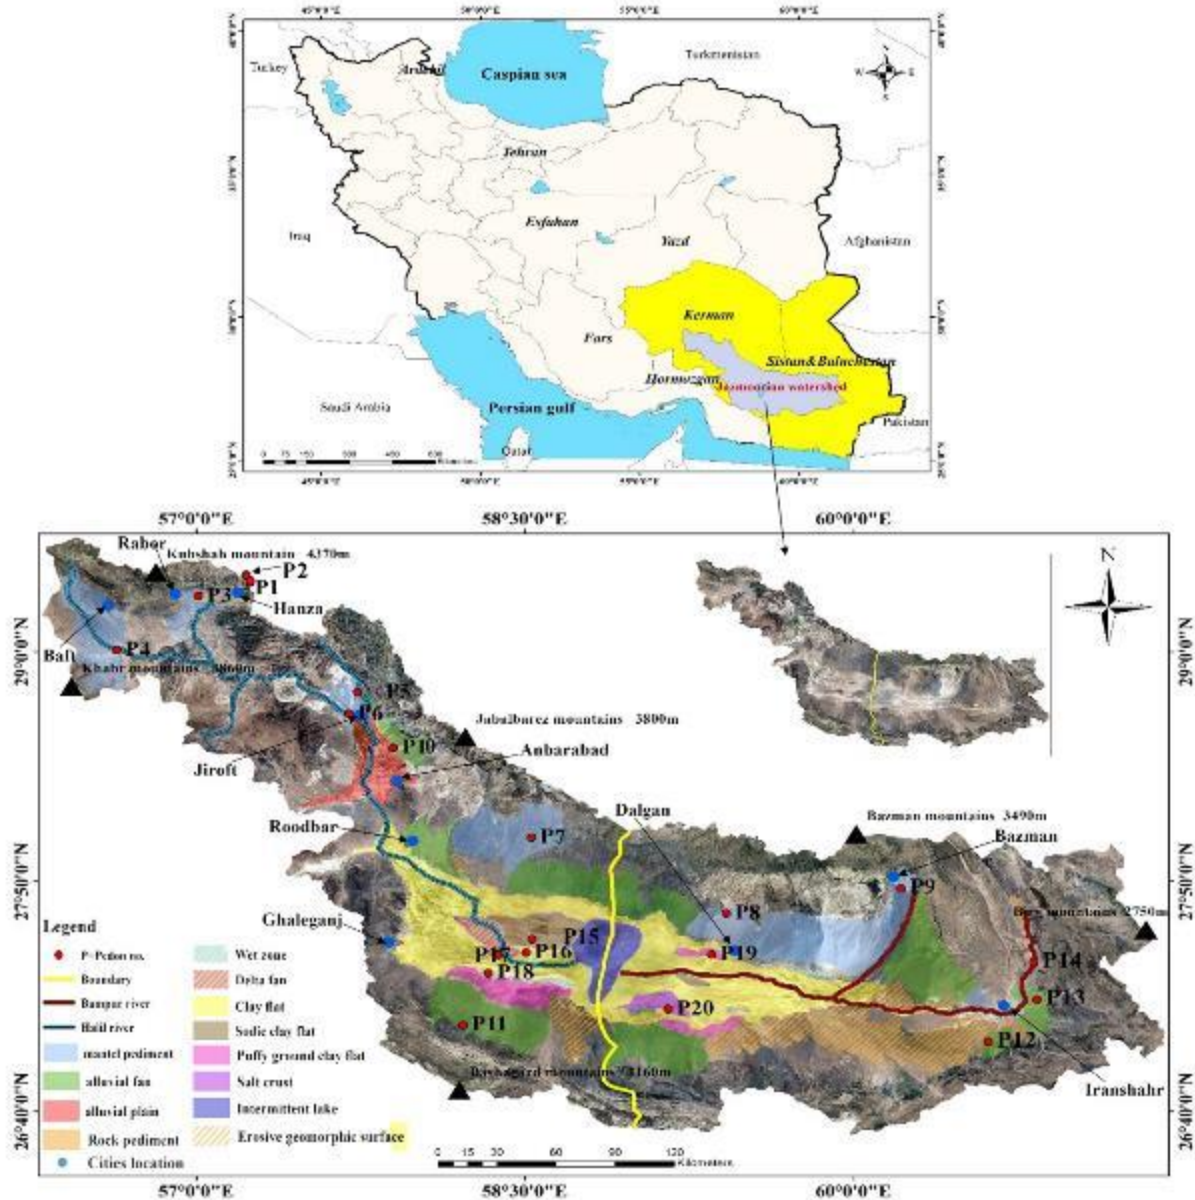

74

75 **2. Materials and methods**

76 **2.1. Study area**

77 Jazmurian Watershed as a part of central Iran, Makran, and southeast Iran zones located in
78 Kerman and Sistan-Baluchestan Provinces (56° E to 62° E and 26° N to 30° N) was selected as the
79 study area (Fig. 1). The maximum elevation in the area is 4400 m above sea level (asl) for the Shah
80 Mountain, Rabor area and the minimum elevation is only 360 m (asl) at Jazmurian Playa. Two
81 main rivers including non-saline Halilrood which heads from Kerman Province elevations (north
82 of the watershed) and saline Bampoor which heads from Iranshahr elevations (east side of the
83 watershed), both end to central lake of Jazmurian Playa (Fig. 1). Jazmurian Playa is a depression
84 of Late Pliocene Era (Namaki 2003). Miocene faulted rocks and evaporites of Upper Red
85 Formations are at the east boundary of the watershed. Jebalbarez igneous mountain (granite, diorite,
86 and andesite) is located at north. Intrusive and external igneous rocks are reported at the west and
87 southeast sides of the area and the Beshagard Paleocene and Cretaceous Ophiolite Mountains
88 together with Mokran colored Melange which separate the watershed from Oman Sea are located
89 at the south (Mohammadi, 2011). Soil mean temperature varies from 13.1 °C in Rabor and Hanza
90 (Mesic soil temperature regime) to 28.9 °C in Iranshahr and Dalgan areas (Hyperthermic soil

91 temperature regime). Mean Annual precipitation also varies from 287 mm in Rabor and Hanza
 92 (Xeric moisture regime) to 82 mm in Roodbar Jonoub areas (Aridic soil moisture regime).

93
 94 **Fig. 1.** The study area, geomorphology map showing location of representative pedons.

95 2.2. Field studies

96 Alluvial fan, rock and mantled pediments, Piedmont plain, playa, and lowland were among
 97 dominant landforms studied after detailed field and aerial photo observations (Fig. 1). Playa was
 98 also divided to clay flat, sodic clay flat, puffy ground clay flat, salt crust, wet zone, fan delta, and
 99 lake geomorphic surfaces. Considering variations in elevation, soil moisture and temperature

100 regimes, and parent material, one representative pedon on each geomorphic surface (total of 20
101 pedons) were selected, described (Schoeneberger et al., 2012), and sampled. Fig. 1 shows the study
102 area and the location of representative pedons.

103 Various soil moisture regimes included; xeric (pedons 1 and 3), aquic (pedons 2, 18) and aridic
104 (other pedons) and temperature regimes included mesic (pedons 1, 3 and 4), thermic (9),
105 hyperthermic (other pedons) related to elevation variations and the vast extent of the area were
106 found (Banaie, 1998).

107

108 **2.3. Laboratory investigations**

109 After sampling, air-dried ground soil samples passed through a 2 mm sieve and the volumetric
110 percentage of coarse fragments was determined. Particle size distribution was investigated using
111 pipet method (Gee and Bauder, 1986). Jenway pH and EC meters were used to determine the pH
112 of saturated paste and the EC of saturated extract, respectively. The sum of gypsum and anhydrite
113 was analyzed using acetone precipitation (Nelson, 1982). Gypsum was investigated using the Oven
114 method (Artieda et al., 2006). Anhydrite was calculated by the subtraction of gypsum from
115 gypsum+anhydrite (Wilson et al. 2013). Back titration of excess NaOH by HCl was used for
116 equivalent calcium carbonate determination (Nelson, 1982). Wet oxidation using potassium
117 dichromate (Nelson and Sommers, 1982) was used for organic carbon determination. Substitution
118 of sodium acetate by ammonium acetate pH=7 was the basis for cation exchange capacity (CEC)
119 determinations (Bower and Hatcher, 1966).

120

121 **Micromorphological study**

122 Undisturbed soil samples were impregnated using a Vestapol resin with acetaeric acid as the
123 hardener and cobalt acetate as the catalyst for micromorphological studies, under vacuum. A BK-
124 POL petrography microscope in plain (PPL) and crossed (XPL) polarized lights was used for thin
125 section observations and interpretations performed by the Stoops (2003) guideline.

126

127 **Clay mineralogy**

128 Soil samples were prepared (Jackson, 1975; Kittrick and Hope, 1963) for XRD analysis and four
129 treatments including Mg-saturated, Mg-saturated and treated by ethylene glycol, K-saturated, and
130 K-saturated and heated up to 550 °C performed on each sample. A Broker DH8 Advance
131 diffractometer with Cu as the target at 40 kv and 30 mA with the scan speed of 0.02 degree per

132 second was used for XRD analyses. The area under first order peaks of Mg saturated-treated by
133 ethylene glycol was used as the reference for semi-quantitative clay mineralogy (Jones et al., 1954).
134 Besides, several bulk soil samples were mounted on Al stubs by a carbon glue, coated with gold,
135 and observed by scanning electron microscope (XL 30 ESEM Philips) as a complementary to clay
136 mineralogy investigations.

137

138 **3. Results and discussion**

139 Table 1 shows selected physiochemical soil properties and soil classifications based on Soil
140 Taxonomy (Soil Survey Staff, 2022) system.

141

142 **3.1. Piedmont Plain**

143 Pedon 1 on this geomorphic position is about 3620 m above sea level (asl) with a xeric moisture
144 regime affected by diorite derived parent material (Fig. 1). Mollic and cambic horizons were
145 determined through field studies, but no calcic or gypsic horizon was found. Gleyic condition
146 caused by textural differentiation was the reason an Oxyaquic Haploxeroll to be formed.

147 Smectite, illite, chlorite, and kaolinite clay minerals were found in the Bw1 horizon and R layer
148 (Table 2) which are accounted as a proof of the inheritance origin of minerals from parent material
149 (Yousefifard et al., 2015). Palygorskite was also found in the Bw1 horizon (Table 2, Fig. 3a). Since
150 palygorskite was neither present in the parent material (Fig. 3b), nor were the environmental
151 conditions in this pedon suitable for its formation due to relatively high precipitation, the detrital
152 origin (aeolian source) in this geomorphic surface could be a plausible reason for palygorskite as
153 also supported by other researchers (Sarmast et al., 2017; Singer, 1989).

154

155 **3.2. Lowland**

156 This geomorphic position with the elevation of 3570 m asl and an aquic soil moisture regime was
157 also affected by diorite parent rock (Fig. 1). Pedon 2 on this surface with Histic and Cambic
158 horizons showed gleyic properties. Water logging together with a cold climate inhibited organic
159 matter decomposition that is why about 16% organic carbon with an intermediate decomposition
160 in this pedon was accumulated and caused Histic Humaquepts to be formed.

161 Illite and kaolinite were the only clay minerals formed in this pedon (Table 2, Fig.3c).
162 Transformation of smectite to kaolinite due to high precipitation rate and low pH (Table 1) in this
163 pedon could not be neglected. This could be the reason why the highest kaolinite content was found

164 in this pedon. On the other hand, lack of palygorskite is attributed to high weathering rate and the
 165 mineralogy of parent material which lacks palygorskite (Moazallahi and Farpoor, 2012).
 166 Transformation of palygorskite to smectite is reported to take place at the annual rainfalls more
 167 than 300 mm (Paquet and Millot, 1972) as a support.

168 Pedons 1 and 2 have the same parent material but different geomorphology and soil moisture
 169 conditions. Since the soils formed on the two mentioned locations are different (Haplustolls vs.
 170 Humaquepts), it is clear that climate (xeric vs. aridic) and topography (piedmont plain vs. lowland)
 171 played an important role on soil genesis and development in the area compared to parent material
 172 (both diorite).

173 **Table 1.** Selected physical and chemical properties of studied pedons.

183

184 3.3. Mantled pediment

185 Mantled pediment covers a vast area in the region. Soils in this landform were affected by igneous
186 (pedons 3 and 8), diorite (pedons 5-7 and 9), and sedimentary limestone (pedon4) parent materials
187 (Mohammadi, 2011) with two xeric and aridic soil moisture regimes. Argillic and calcic horizons
188 were found in most pedons under study, but gypsic horizon was only found in the parts with an
189 aridic soil moisture regime (Table 1). The argillic horizon (Fig. 2a) in the xeric parts of the area
190 (pedon 3) could be due to the present humidity of the area, whereas argillic in other pedons with
191 an aridic moisture regime, could only be attributed to the more available humidity of the past.
192 Evidence of more humid paleoclimate in central Iran was reported by other researchers (Farpoor
193 et al., 2012; Khormali et al., 2003; Khademi and Mermut, 2003).

194 Calcium carbonate equivalent (CCE) increased with depth (Table 1) in pedon 4 due to the
195 presence of a calcareous parent material (about 89% in 2Ckk horizon). Besides, natric, salic, and

196 anhydritic horizons were also investigated in mantled pediment position. Anhydrite in pedons 7
197 and 8 was probably formed from dehydration of gypsum at the later stages of evaporation through
198 evolution of the landform. High temperature caused this mineral to be preserved (Sarmast et al.,
199 2017; Wilson et al., 2013).

200 Pedons 3 and 8 with the same parent material (andesite) showed different evolutions. Pedon 3 in
201 the xeric part of the area had an argillic horizon, whereas no argillic was found in aridic parts with
202 about 1800 m asl. Climate seems to be the only factor controlling soil evolution in these pedons.
203 Pedon 3 is an Alfisol, but the other pedons were classified as Aridisols (Table 1).

204 Micromorphological observations showed clay (pedons 3-7 and 9), calcium carbonate (pedons 3-
205 4 and 9), gypsum (pedons 5, 8-9), anhydrite (pedon 7), and compound (pedons 3 and 9) pedo-
206 features (Fig. 2). Clay coating in pedon 3 (Fig. 2a) with a xeric soil moisture regime was probably
207 formed in the present climatic conditions of the area. On the other hand, argillic horizon formation
208 and clay coatings (Figs. 2 b, e, g, i, l, m) in other pedons in this landform with an aridic soil moisture
209 regime could only be attributed to the presence of a more humid climate in the past. This was also
210 supported by Farpoor et al. (2012), Sanjari et al. (2011), and Kademi and Mermut (2003) in Sirjan
211 playa, Jiroft, and Isfahan arid areas of central Iran, respectively. A different clay coating in
212 2Bt_{nk}k1 horizon of pedon 4 was observed (Fig. 2c) which was affected by high Na content. This
213 type of clay coatings was reported for the natric horizons where dispersion was induced by Na. The
214 same results were also reported for saline and sodic soils of Fars Province by Khormali et al. (2003).

215 Calcite coatings were observed on the clay coatings in B_{tk} horizon of pedon 3 (Fig. 2a) and B_{tky}
216 horizon of pedon 9 (Fig. 3m). The mentioned order of coatings in pedon 3 could be formed at the
217 climatic situations of the present time, but for the pedon 9 is a proof of clay illuviation during more
218 available humidity of the past, followed by calcite illuviation along later aridity as was also
219 supported by Bayat et al. (2017) and Moghbeli et al. (2019). The compound clay-calcite pedo-
220 feature is a proof of the formation of a polygenetic soil which has experienced different formation-
221 development cycles due to climatic fluctuations.

222 Calcite coatings (Figs. 2a, d, m, o) are among the most important pedo-features which have
223 formed through re-precipitation of illuviated calcium carbonates originated from upper horizons
224 (Kemp et al., 2003). Dissolved calcium carbonate in the arid climate of the present time has formed
225 infillings (Fig. 2d, o) in the pore spaces (Durand et al., 2010). Sarmast et al. (2019) reported coating,
226 infilling and nodule pedo-features of calcite in soils of central Iran.

227 Meanwhile, lenticular and interlocked plates of gypsum (Fig. 2f) in By horizon of pedon 5 on
228 mantled pediment were investigated. Soils of this pedon were not saline (Table 1) and were
229 composed of high sand and coarse gravel contents. Large pore space content of the soil could
230 facilitate lenticular formation of gypsum as was also supported by Amit and Yaloon (1996) and
231 Farpoor et al. (2012) in Israel and central Iran, respectively. The same mechanism could also be
232 attributed to the lenticular gypsum formation in Btky horizon of pedon 9 (Fig. 2k). Gypsum
233 pendants (macroscopic form) and gypsum interlocked plates (microscopic form) in pedons 5 and
234 8 were attributed to coarse texture and high gravel content of pediments (Farpoor et al., 2003).
235 Meanwhile, anhydrite was also formed in By1 horizon of pedon 7 (Fig. 2h), seemingly during
236 gypsum transformation. The same results were reported by Aref (2003) and Sarmast et al. (2019)
237 in soils of Egypt and central Iran, respectively.

238 Smectite, illite, and kaolinite clay minerals were found in pedon 3 (Table 2, Fig. 3d). Palygorskite
239 and chlorite could not be formed or have been weathered in this position due to a xeric moisture
240 regime. Smectite is the dominant clay mineral in this pedon (Table 2). Moreover, smectite, illite,
241 chlorite, kaolinite, and palygorskite were found in soil (Btk1) and parent material (2Ck) of pedon
242 4 (Table 2. And Figs. 3e, f). The presence of the above-mentioned minerals in soils and parent
243 material is a proof of inheritance origin from sedimentary formations which was also supported by
244 Owliaie et al. (2018) for soils located on sedimentary formations of southwest Iran.

245 On the other hand, smectite, illite, chlorite, palygorskite, and kaolinite clay minerals were
246 identified in other pedons (5-9) on this landform which were affected by igneous formations (Table
247 2, Figs. 3 g, h, i, j, k, l). No palygorskite was found in the igneous parent material (Fig. 2b), but
248 calcic (Fig. 3i) and gypsic (Fig. 3j) horizons contained palygorskite. Geochemical conditions after
249 the precipitation of calcium as calcium carbonate and gypsum in the arid climate of these pedons
250 seem to have been favorable for palygorskite formation together with the increase of soluble Mg
251 (Singer and Fine, 1989). A pedogenic origin for palygorskite in calcic (2Btk) horizon of pedon 6
252 (Fig. 4a) and gypsic horizon (Bty) of pedon 7 (Fig. 4b), both affected by igneous formations was
253 proved using electron microscope observations. Preservation of palygorskite around calcite
254 (Khademi and Mermut, 1998) and gypsum (Owliaie et al., 2018; Moazallahi and Farpoor, 2012;
255 Khademi and Mermut, 1998) crystals in soils and sediments of central Iran were also reported.
256 Moreover, the lack of palygorskite and chlorite in the modern topsoil of pedon 6 (Fig. 3h) could be
257 attributed to the Halilrood River floods which may have caused their transformation to smectite

258 (Birkland, 1999). Smectite is the dominant mineral in the modern topsoil of pedon 6 (Table 2)
 259 which is another support for the above-mentioned discussion. Thus, both pedogenic and inherited
 260 origins for smectite in soils of the area are plausible (Sanjari et al., 2011).

 271 crystals in 3Btznb1 horizon, pedon 16 (XPL), r) Lenticular gypsum crystals in Bz2 horizon, pedon 20 (XPL).

304 Pedons 3 and 8 with the same parent material and geomorphology, but different soil moisture
305 regime, have different soils. This is a proof for the important role of climate in soil formation
306 compared to p (parent material) and r (relief) as soil forming factors in this part of the area. On the
307 other hand, pedons 4 to 9 have the same geomorphology and climate, but parent material for pedon
308 4 (limestone) is different with other pedons (diorite). Results clearly show that somehow similar
309 soils were formed in these pedons and limited differences in the suborder level were only observed.
310 This in turn shows the high effective role of climate and geomorphology on soil formation in this
311 landform.

312

313 **3.4. Alluvial fan**

314 Similar to mantled pediment, soils with various evolution were found in this landform. Soil
315 moisture regime for alluvial fan is aridic which is why different soil evolutions (pedons 10-13)
316 could be due to the difference in parent material (Table 1). Pedons 10 (east of Jiroft) and 13 (east
317 of Iranshahr) located on young alluvial fan deposits and affected by granite formations showed
318 very little soil development. The large distance from Neogene gypsiferous and saline formations
319 on one hand, and the young Quaternary alluvial fan deposits on the other hand, are among the
320 inhibiting factors controlling soil development in this geomorphic position. Moreover, the
321 formation of bajada due to rainfall and the erosion of upland mountains in these two locations
322 which are in the arid zone climate, could be evidence of a more humid climate in the past. The
323 same results were also reported by Sarmast et al. (2017) in the study of alluvial fans in the central
324 parts of Iran. Pedons 11 (with argillic and calcic horizons) and 12 (with calcic horizon) respectively
325 affected by limestone and diabase (influenced by Mokran colored melange) parent materials
326 showed soils with high and intermediate evolution located on old alluvial fan deposits.
327 Micromorphological observations showed clay coatings and infillings in Btk horizon of pedon 11
328 (Fig. 2n) which are supporting proofs of argillic horizon formation. Calcite coating, infilling, and
329 nodules were also determined in Bk horizon of pedon 12 (Fig. 2o). Formation of calcite nodule
330 (Fig. 2o) in the Btk horizon of pedon 12 was due to dissolution/recrystallization of calcite in the
331 groundmass. Sarmast et al. (2019) reported coating, infilling and nodule pedo-features of calcite in
332 soils of central Iran. Entisols and Aridisols were formed on this geomorphic position.

333 Pedons 10 to 13 have the same geomorphology (alluvial fan) and climate (aridic soil moisture
334 regime), but different parent material (igneous in pedons 10 and 13 vs. sedimentary in pedons 11

335 and 12). Formation of different soils is a proof of the role of parent material and time on soil
336 formation when other soil formation factors are the same.

337

338 **3.5. Rock pediment**

339 This geomorphic position about 800 m asl and with an aridic soil moisture regime is affected by
340 limestone together with shale and marl as parent material. Pedon 14 with argillic, calcic, and gypsic
341 horizons were described and sampled on this position. Due to low SAR content (Table 1) and an
342 aridic soil moisture regime, presence of argillic horizon similar to other arid parts of Jazmurian
343 Watershed was attributed to the more available humidity of the past. That is why this soil was
344 accounted as a paleosol. Removal of calcium carbonate from upper horizons with more humidity
345 of the past (Bk horizon formation) followed by clay illuviation caused Btk horizon to be formed
346 (Sanjari et al., 2011). Clay coating proved illuviation of clay and argillic horizon formation (Fig.
347 2p). Clay mineralogy of this soil was similar to mantled pediment position (Table 2, Fig. 3m). This
348 soil was classified as Typic Calcigypsid.

349

350 **3.6. Playa**

351 Sodic clay flat (pedon 15), clay flat (pedon 16), fan delta (pedon 17), wet zone (pedon 18), puffy
352 ground clay flat (pedon 19), and salt crust (pedon 20) geomorphic surfaces were found in playa
353 about 360 m asl (Fig. 1). Salic and natric were the dominant horizons found in soils of this
354 landform. High Na content caused clay dispersion and natric horizon formation in some pedons of
355 this position as was also supported by Khormali et al. (2003). A modern and a buried paleosol were
356 found (pedon 16) on clay flat geomorphic position. The modern soil with A and C horizons was a
357 young soil affected by alluvial deposits, and 2Cz horizon showed the influence of aeolian deposits.
358 Active wind erosion of the upland positions caused wind-blown deposits in this horizon. On the
359 other hand, the buried soil is a developed soil with salic and natric horizons. Meanwhile, a non-
360 saline (Table 1) Fluvisol (pedon 17) was found on fan delta geomorphic surface. Formation
361 processes of fan delta position and the role of Halilrood River with a non-saline water, could be
362 accounted for a non-saline soil to be formed in pedon 17.

363 Wet zone with an aquic soil moisture regime was located between alluvial fan and clay flat
364 positions. The same geomorphic position was also reported by Farpoor et al. (2012) in Sirjan Playa.
365 High electrical conductivity (EC) in the topsoil of puffy ground clay flat was attributed to
366 evaporation and capillary water movement in this geomorphic position (Sanjari et al., 2011). The

367 thickness of salt polygons in the salt crust geomorphic position of the area was less than what
368 reported for other playas (Sirjan, and Lut) of central Iran. Bampour seasonal river which has passed
369 through evaporate formation of east side watershed contains more soluble salts compared to non-
370 saline Halilrood River. Salt crust seems to be affected by Bampour River. Soils of this position
371 were classified as Entisols and Aridisols (Table 1).

372 Lenticular gypsum crystals observed in 3Btznb1 (pedon 16) and Bz2 (pedon 20) horizons. Soils
373 in this position were fine textured with small pore spaces and high salinity (Table 1). The reason
374 could be attributed to the NaCl content (Amit and Yaloon 1996) together with super saturation in
375 respect to calcium sulfate in the fine pore spaces along time periods (Owliaie et al. 2006). Since
376 gypsum content was not enough, gypsic horizon was not detected in these pedons.

377 Palygorskite was not detected in Btzn2 horizon of pedon 18 on wet zone geomorphic position
378 (Fig. 3o). Due to high humidity content in this position (presence of an aquic soil moisture regime),
379 transformation of palygorskite to smectite which was also reported by Khormali and Abtahi (2003)
380 and Moghbeli et al. (2019) could not be neglected in this position. The dominance of smectite in
381 this soil (Table 2) could be another support for the above-mentioned discussion. Since smectite
382 was also determined (Fig. 3n) in the Bz horizon (near the soil surface), it seems that the detrital
383 origin of smectite addition to the surface could be another plausible reason. The intense 0.63 nm
384 peak of palygorskite was also due to the detrital transportation of broken palygorskite crystals from
385 alluvial fan toward this position. That is why palygorskite in this geomorphic position is with a
386 detrital origin which was also supported by split crystals observed using electron microscopy (Fig.
387 4). Farpoor and Irannejad (2013) and Khademi and Mermut (1998) also came to the same
388 conclusion in Rafsanjan and Isfahan areas, central Iran.

389 Parent material and climate for pedons 15 to 20 are the same, but geomorphic surfaces have only
390 changed which caused differences in order and suborder levels of soils formed in playa. This shows
391 the role of topography (r) apart from climate and parent material in soil formation.

392

393

394
 395 **Figure 4.** SEM micrographs of (a) palygorskite fibers on calcite crystal of the 2Btk horizon of pedon 4, (b) palygorskite
 396 fibers on gypsum crystal of the Bty horizon of pedon 5, (c) palygorskite broken fibers of the Bzn horizon of pedon 18.
 397

398 4. Conclusions

399 Various soils were formed through the climolithotoposequence studied in Jazmurian Watershed.
 400 The electrical conductivity content increased toward playa and the maximum EC content of 222.2
 401 dS/m was determined in salt crust geomorphic position of playa. Soil evolution was highly
 402 depended on parent material and the decreasing trend of soil evolution (granite-young alluvial fan
 403 deposits < playa deposits < limestone-old alluvial fan deposits < andesite- diorite) was found in the
 404 area. Soils were classified as Mollisols, Alfisols, Aridisols, Inceptisols, and Entisols. Different
 405 pedofeatures in argillic and calcic horizons in both xeric and aridic soil moisture regimes of the
 406 area were found. However, pedo-features related to gypsic and anhydritic horizons were only found
 407 in the arid parts of the transect. The presence of a more humid paleoclimate in the history of the
 408 area which was supported by clay coatings was proved by argillic horizons formed in the arid parts
 409 of the area. A dispersed clay coating was found in natric horizons. Smectite, illite, chlorite,
 410 palygorskite, and kaolinite clay minerals were identified. Palygorskite was only found in the arid
 411 parts of the area and pedogenic and inherited origins were respectively found in igneous and
 412 sedimentary affected soils. Palygorskite in piedmont plain about 3620 m asl was with an aeolian
 413 origin. Illite and chlorite clay minerals were identified in both sedimentary and igneous parent
 414 materials with an inherited origin, but lack of these minerals in some of the soils under study could
 415 be attributed to their transformation to smectite which was also supported by smectite peak

416 intensity in such soils. That is why both inherited and transformed (from illite, chlorite, and
417 palygorskite) sources of smectite in the area were plausible.

418 Results of the study emphasized on the more effective role of climate and relief on soil formation
419 compared to parent material. The role of climate, alone or together with relief on soil formation
420 and evolution in pedons 1 to 9 seems to be greater than that of parent material. Since climate and
421 relief have not changed along pedons 10 to 14, parent material affected soil formation and
422 evolution. Moreover, relief has controlled soil formation and development in pedons 15 to 20 as
423 climate and parent material were the same in these pedons. The hypothesis regarding the effects of
424 climate, topography, and parent material soil forming factors on soil formation and development
425 (climolithotoposequence) in the area was clearly proved.
